
NUCLEAR GOVERNANCE ARCHITECTURE AND ITS LIMITS FOR AI VERIFICATION

Andrew Ayobami

ABSTRACT

Proposals for an "IAEA for AI" and broader analogies between AI and nuclear arms control assume that nuclear agreements embody a distinct design template from other arms control regimes, and that this template can be transplanted into AI governance. This paper tests those assumptions directly through an empirical comparison of nuclear and non-nuclear arms control agreements using the Alva Myrdal Centre Arms Control Agreement Database. Focusing on inspector arrangements and trigger mechanisms, we find quantitative support for the first assumption. Nuclear agreements are more reliant on party-on-party inspections, treaty-protected national technical means (NTMs), layered verification systems, and cooperative or pre-consented trigger mechanisms than non-nuclear agreements, a difference confirmed by Fisher's Method across combined tests ($p \approx 0.005$). On the second assumption, transferability is more uneven and conditional than AI governance proposals typically acknowledge. Most nuclear features that transfer cleanly—NTM-style remote sensing, baseline declaration systems, notification regimes, and activity-window access for high-risk events—transfer plausibly at the hardware layer of AI governance, particularly for datacenter monitoring, semiconductor governance, baseline infrastructure declarations, and compute-related notification systems. Features that depend on the physical traceability of nuclear materials—such as precise capability thresholds as treaty triggers—transfer poorly or not at all. We conclude that a nuclear-modeled AI governance architecture would be hardware-centric by design and meaningful within that scope, but would leave the deeper verification problem structurally unresolved.

1. INTRODUCTION

As AI systems demonstrate capabilities with potentially profound economic and security implications, the question of how the international community might verify compliance with any future AI governance agreements has become pressing. Policymakers and technical experts are now actively grappling with verification architectures that did not need to exist a decade ago.

In reaching for precedents, one comparison dominates the discourse. Despite clear differences in the underlying technology, the actors involved, and threat models, nuclear governance looms larger than any other historical regime in contemporary AI governance debates. The differences are not trivial: nuclear weapons were developed and controlled by states, whereas advanced AI is largely driven by private firms; nuclear risks manifest through physically traceable material chains, whereas AI risks emerge from software systems that leave no equivalent physical signature; and nuclear capability was concentrated in a handful of identifiable programs, whereas AI development is geographically and institutionally diffuse. Yet, comparisons which invoke the verification logic of nuclear arms control for AI, including proposals for an “IAEA for AI” (Krawec, 2025), recur persistently across policy documents and academic literature (Hatz, 2025).

These invocations typically rest on two compounding assumptions: first, that nuclear arms control agreements have a governance design template that is meaningfully distinct from those of other arms control regimes; and second, that the features of this template can be transplanted into the domain of AI governance (Baker, 2023). Often, both assumptions are treated as premises rather than as propositions to be tested. In this paper, we test them directly.

We do so through a structured empirical comparison of nuclear and non-nuclear arms control agreements, focusing on two dimensions of governance design that are most diagnostic for verification: (1) inspector arrangements and (2) trigger mechanisms. Inspector arrangements concern who conducts verification and under what institutional form. Trigger mechanisms concern the conditions under which compliance scrutiny is activated — that is, whether monitoring is automatic, self-enforced, contingent on state action, or dependent on political demand. Together, these dimensions determine both the structural independence of verification and its operational reliability. We assess whether nuclear agreements are statistically distinct from non-nuclear agreements on these dimensions, and then evaluate which features of the nuclear model transfer meaningfully to AI governance and which do not.

Our comparison class for non-nuclear agreements is chemical and biological weapons governance. This choice is deliberate and analytically motivated on two grounds. First, advanced AI is increasingly framed in security discourse as a weapon-of-mass-destruction-adjacent technology. AI governance scholarship portrays AI through the lens of catastrophic and even existential risk (Hendrycks, 2023). The plausible use of AI to accelerate biological and chemical weapons design (Turner, 2026; Dance, 2026)—potentially enabling mass destruction—ranks among the scenarios most consistently identified in AI risk literature (Hendrycks, 2023). Secondly, the verification difficulties associated with chemical and biological weapons—for example, dual-use production facilities, the inadequacy of material accountancy, the difficulty of distinguishing offensive from defensive programmes, and rapid scalability—bear a resemblance to the verification challenges that AI governance will face. If AI will be governed through frameworks designed for technologies capable of catastrophic harm, then the governance architecture of chemical and biological agreements constitutes the most relevant comparison class.

Likewise, our focus within nuclear agreements is bounded. We examine agreements involving the United States, Russia, and China. This scoping reflects the governance reality of both the nuclear era and the emerging AI era. Nuclear arms control was shaped most consequentially by the United States and the Soviet Union, with China occupying a more limited role in early multilateral instruments. Advanced AI development today is similarly concentrated: the United States and China account for the dominant share of frontier model development, compute infrastructure, and AI-relevant semiconductor production, with the United Kingdom holding a more limited but significant position.

The design features of arms control agreements reflect the strategic concerns and bargaining dynamics of the parties who negotiated them. However well-designed, agreements between smaller or middle powers may miss nuances between the most technologically advanced and geopolitically competitive powers with both the capability to develop the most advanced systems and the strategic incentive to resist constraints on that capability—actors which we expect to exert more influence on the formation of AI agreements. Therefore, their governance architectures encode assumptions about institutional trust and verification access that may not obtain in the relationships that will define advanced AI governance. By focusing on agreements that capture the power asymmetries and adversarial trust conditions of superpower negotiation, we aim to maximize the relevance of the historical precedents to the governance context that may matter more for AI.

The remainder of the paper proceeds as follows. The Methods section describes the dataset and scoping decisions. In the Findings section, we present our empirical comparison across inspector arrangements and trigger mechanisms, including a combined test for statistical difference. The AI Governance Lessons section assesses transferability — which nuclear governance features can plausibly be adapted for AI verification, and in what specific respects. The Limitations section addresses constraints on the analysis, including the dataset imbalance between nuclear and non-nuclear agreements. We conclude by drawing together the implications of the findings for the design of AI governance regimes.

2. METHODS

This study relies on the Alva Myrdal Centre Arms Control Agreement Database (V2), which provides variable-level data on the governance design features of international arms control agreements, including verification compliance (vercom) and demonstrated compliance (demcom) profiles. We mapped 16 agreements across two analytical groups. The nuclear group comprises agreements meeting either of two criteria: (1) multilateral agreements involving all three of the United States, Russia, and China, whom we identify in the introduction as the three states most central to nuclear governance design or (2) bilateral agreements between any two of these three states. This yielded 13 nuclear agreements:¹ Anti-Ballistic Missile Treaty (1972); Accidents Measures Agreement (1971); Ballistic Missile Launch Notification Agreement (1988); Comprehensive Nuclear Testban Treaty (1996); INF Treaty (1987); MSE Agreement: Agreement On Reciprocal Advance Notification Of Major Strategic Exercises (1989); NEW START (2010); Outer Space Treaty (1967); Peaceful Nuclear Explosions Treaty (1976); Seabed Treaty (1971); START I (1991); START II (1993); Threshold Test Ban Treaty (1974). The non-nuclear group comprises

¹ The analysis excludes agreements that lack both vercom and demcom profiles in the AMC dataset. This means several institutionally significant instruments — including the IAEA Comprehensive Safeguards Agreement system — are not directly represented in the findings. The implications of this and other dataset constraints are discussed in the Limitations section [page 12].

chemical and biological weapons agreements, selected as the most analytically comparable non-nuclear weapon category for reasons set out in the introduction. This yielded 3 agreements: the Biological Weapons Convention (BWC), the Chemical Weapons Convention (CWC), and the US-USSR Bilateral Destruction Agreement (BDA).

Analysis focused on two governance design dimensions: inspector arrangements² and trigger mechanisms.³ Across both design dimensions, we observe 119 compliance mechanisms in nuclear (105) and non-nuclear (14) agreements to assess whether nuclear agreements are significantly distinct from non-nuclear agreements. Because several comparison categories involved small sample sizes and sparse contingency tables, statistical significance was assessed using Fisher's Exact Test rather than chi-square tests. Individual p-values from these tests were then aggregated using Fisher's Method ($X^2 = -2\sum \ln(p_i)$) to produce a combined significance value across all comparisons, allowing an overall assessment of whether the observed differences between nuclear and non-nuclear governance architectures are likely to reflect systematic design divergence rather than random variation.

3. FINDINGS

The design of arms control agreements codify governance choices on who conducts verification; under what conditions scrutiny is activated; and what compliance obligations are self-executing versus contingent on political will. Two dimensions of this design are particularly diagnostic for assessing whether nuclear agreements constitute a distinct governance template: (1) inspector arrangements, which concern the identity, rights and institutional standing of the verifying actor, and (2) trigger mechanisms, which concern the conditions under which compliance scrutiny is initiated. We examined both dimensions across the 16 mapped agreements, comparing nuclear and non-nuclear agreements on each, to test the assumption that nuclear agreements meaningfully differ from other arms control agreements. Here is what the data suggests:

3.1 Inspector Arrangements

3.1.1 Nuclear agreements differ from other WMDs in inspector type.

In nuclear agreements, the predominant inspector type is party-on-party, an arrangement where one state party conducts inspections on another party. All 10 nuclear agreements with verification profiles in the dataset use this arrangement, and 9 of them use it exclusively. The only exception is the Comprehensive Nuclear-Test-Ban Treaty (CTBT), which adds an agreement-established body (CTBTO) for in-person inspections, alongside party-on-party for NTMs. Here, nuclear agreements contrast sharply with other WMDs. Only one non-nuclear agreement uses the party-on-party inspector type—the BDA. BWC utilizes the United Nations Security Council (UNSC) as its inspector, while the CWC established the Organisation for the Prohibition of Chemical Weapons (OPCW) for this purpose. Importantly, although the

² For inspector arrangements, the relevant variables included inspector type, whether a standing inspection body was established or utilised, the breadth of verification tools employed, and the use of National Technical Means (NTMs) and NTM non-interference provisions.

³ For trigger mechanisms, analysis drew on both vercom and demcom profiles, covering trigger type classifications, conditions which activate specific treaty obligations, cooperative versus unilateral trigger distributions, and trigger type use in specific compliance lifecycle stages.

predominance of party-on-party inspectors in nuclear agreements points toward a substantively large difference, the result does not reach the level of statistical significance under Fisher's Exact Test (two-tailed $p \approx 0.08$), largely because of the very small non-nuclear sample.

It is necessary to add that the predominance of party-on-party inspector type in nuclear agreements may also be a product of laterality, rather than mere nuclear distinctiveness. 7 out of 10 nuclear agreements analyzed here are bilateral. Every bilateral nuclear agreement uses party-on-party inspection without exception. Anti-Ballistic Missile Treaty (ABM), Threshold Test Ban Treaty (TTBT), Peaceful Nuclear Explosions Treaty (PNE), Intermediate-Range Nuclear Forces Treaty (INF), START I, START II, and New START all code exclusively as party-on-party, with no established body and no utilized association. Interestingly, this pattern also extends to the bilateral BDA, a chemical weapons agreement which stands apart from other non-nuclear agreements in its non-use of institutions as inspectors. Crucially, it is also the only bilateral non-nuclear agreement. However, this caveat is undermined by the fact that all three multilateral nuclear agreements—CTBT, Seabed Treaty and Outer Space Treaty—also use party-on-party inspector type, and the latter two use it exclusively. This suggests that nuclear agreements may distinctly favour party-on-party inspector arrangement regardless of laterality.

The correlation between bilateral agreements and party-on-party inspector type is not coincidental. Bilateral agreements between superpowers involve mutual mistrust at the highest political level, but also a kind of mutual accountability that makes third-party inspection politically toxic to both sides. The US and the USSR may be more likely to accept an arrangement where each side gets symmetrical access into the other than one where a third party observes their most sensitive military facilities. Should AI systems evolve into strategically consequential technologies with immense military ramifications, as some scholars have postulated (Hendrycks, 2025), this logic may apply equally to future AI governance arrangements involving the US and China. By and large, the nuclear model is predominantly party-on-party, which is the opposite of what "IAEA for AI" proposals imply when they invoke nuclear governance.

3.1.2 The physical nature of nuclear programs creates reliance on NTM non-interference clauses.

The cleanest binary split between nuclear and non-nuclear agreements is the use of NTM non-interference clause in the former. Among agreements with verification profiles in the AMC dataset, 8 out of 10 nuclear agreements explicitly mention non-interference with NTMs; the only exceptions being the Outer Space and Seabed treaties—two agreements which predate the first codification of NTMs into a nuclear agreement in 1972. Fisher's Exact Test indicates that this difference is unlikely to be due to random variation (two-tailed $p \approx 0.03$). A possible explanation for the absence of NTMs in the Seabed Treaty is that although NTMs existed, they were poorly suited to seabed verification, as satellites cannot see through deep ocean water and acoustic signals underwater are noisy and hard to attribute.

In contrast, no non-nuclear agreement includes an NTM non-interference clause or mention NTMs at all. With respect to monitoring and verification, this is arguably the most architecturally distinctive feature of the nuclear governance model relative to non-nuclear WMDs. Nuclear agreements treat satellite surveillance and seismic monitoring as treaty-protected, legally recognized verification tools. Non-nuclear agreements do not. The ABM Treaty in 1972 was the first to codify this. Every subsequent bilateral nuclear agreement inherited that design.

This disparity reflects the physical differences between nuclear programs on one hand and chemical and biological programs on the other. Nuclear facilities are large and visible from orbit. Satellites can see missile silos, test sites, and submarines. Therefore, the NTM clause was practically valuable (as satellites were already monitoring) and politically necessary since each side needed assurance the other wouldn't tamper its surveillance capability and cheat. Conversely, chemical and biological programs are smaller, more concealable, and less reliably detectable by satellite. Hence, NTM protection wasn't as central to their verification logic.

3.1.3 Nuclear agreements use a wider breadth of inspection tools.

The majority of nuclear agreements we observe combine more inspection/verification categories than agreements on other WMDs, although this pattern is not true of every single nuclear agreement. The BWC and BDA use only one inspection tool—in-person inspection. Alongside in-person inspection, the CWC also uses in-person monitoring, totaling two verification categories in all. Nuclear agreements differ on average in this regard. START I uses five distinct verification categories: in-person inspection, in-person exhibition, remote monitoring, display, as well as NTMs. INF Treaty uses four, while New START and CTBT use three.

The keynote of this broader pattern is the distinctiveness of nuclear arms reduction agreements, not just from other nuclear agreements but from all observed WMDs agreements. The agreements with the broadest breadth of inspection tools all happen to be treaties which focus on limiting and reducing the number or types of deployed nuclear warheads or nuclear delivery vehicles owned by the US and USSR/Russia. START I (5), INF (4), and NEW START (3) all function as arms reduction agreements. Although the INF Treaty prohibits a class of weapons (ground-launched ballistic and cruise missiles with ranges of 500-5500km) and required their complete elimination within three years, it was operationalized as a reduction agreement, as it needed to verify a reduction process to completion.

Such agreements are differentiated from prohibition/ban agreements, which typically use a narrower breadth of inspection tools. Outer Space Treaty, Seabed Treaty, BWC and BDA—all prohibition agreements—utilize only in-person inspections. The CTBT—an agreement prohibiting all nuclear test explosions—is an exception here, with three utilized verification categories (In-person inspections, remote monitoring and NTMs). Similarly, the ABM Treaty—unlike other nuclear arms reduction agreements—utilizes only NTMs, without any real inspection tools. We explain this anomaly by pointing out that the number and location of defensive systems are large, fixed and, therefore, visible by satellite. Since the objects being verified (radar installations, missile interceptor sites) were inherently NTM-verifiable, no in-person inspection was needed. Despite these two notable exceptions, the observation that nuclear arms reduction agreements use more inspection tools than others generally holds.

This pattern reflects the significance of verification complexity. Arms reduction treaties reduce specific quantities of highly technical delivery systems across multiple basing modes (land, sea, air), while allowing continued possession of others. Verifying that a specific number of SS-18s have been eliminated but a different number of SS-25s remain requires multiple complementary tools: inspectors to count and confirm destruction (in-person inspection), exhibitions to confirm technical characteristics (in-person exhibition), portal monitoring to catch undeclared production (remote monitoring/display) and satellites to

monitor movement (NTMs). By contrast, arms prohibition agreements have a simpler binary task which requires fewer verification layers.

3.1.4 In-person type inspections in nuclear agreements penetrate more stages of the compliance lifecycle, but only slightly.

The use of in-person type inspections (exhibitions, monitoring, inspections) highlight another key—though slight—design difference across nuclear and non-nuclear agreements. In more intrusive verification models, inspections may appear across all four phases of compliance identified in the AMC dataset: initiated, updated, challenge and completed. This would mean that the inspecting authority is expected and empowered to observe:

- the starting baseline
- ongoing behavior
- suspicious deviations
- and final dismantlement

Some of the agreements which reach anything close to this full-spectrum inspection coverage are nuclear agreements, although some function-specific nuclear treaties (e.g. Threshold Test Ban Treaty and Peaceful Nuclear Explosions Treaty) span only one compliance phase. The strongest case is START I, the only agreement with in-person arrangements that span all four phases. New START Treaty comes close, with in-person exhibitions and inspections across the initial, updated and completed phases. However, chemical weapons agreements notably equals and outranks some nuclear agreements. In-person monitoring and inspections in the CWC spans three phases (initiated, updated and challenged), while the BDA arrangement spans two phases, which is as encompassing as the arrangement in the INF, START II and Seabed agreements.

In the BWC, inspections only appear under challenge compliance. And even that is politically mediated, since the only pathway to bring about inspections is through the UNSC. This would require consensus among permanent members with veto powers that are often exercised in furtherance of political interests and alliances. Unsurprisingly, in over 50 years of the treaty's existence, no genuine challenge inspection has ever occurred, despite an unprecedented and unsuccessful invocation of the Article VI UNSC provision by Russia in 2022.

3.2 Trigger Mechanisms

3.2.1 Nuclear agreements rely more on pre-consented and automatic triggers.

In nuclear agreements, compliance mechanisms are overwhelmingly triggered by the agreement itself or by the inspected state's own actions — more than by the discretion of a suspecting state-party. Agreement triggers are admittedly not unique to nuclear agreements; 35.7% of compliance mechanisms in non-nuclear agreements are triggered by agreement, compared with 32.4% in nuclear agreements.

Trigger Type	Nuclear (n = 105)	% Nuclear	Non-nuclear (n = 14)	% Non-nuclear
Agreement	34	32.4%	5	35.7%
State-party action	31	29.5%	1	7.1%
State-party notification	20	19.0%	2	14.3%
State-party request	9	8.6%	2	14.3%
Circumstance	4	3.8%	2	14.3%
Agreement association	2	1.9%	0	0%
Other	5	4.8%	2	14.3%

Table 1: Distribution of trigger mechanism types across nuclear and non-nuclear agreements.

However, to understand the nature of trigger mechanisms across both weapon categories, we further classified trigger types into:

- **Pre-consented/cooperative triggers** (states agreed at signature, with no further political decision required): Agreement, state-party notification, state-party action
- **Unilateral/reactive triggers** (often requiring a unilateral decision to invoke): State-party request, agreement association, circumstance

	Nuclear	Non-nuclear
Cooperative triggers	85 (81.0%)	8 (57.1%)
Demand/reactive triggers	15 (14.3%)	6 (42.9%)
Other	5 (4.8%)	2 (14.3%)

Table 2: Distribution of cooperative and reactive trigger mechanisms across nuclear and non-nuclear agreements. Cooperative triggers include pre-consented and self-executing mechanisms activated by agreement design or routine state actions, while reactive triggers involve politically activated or demand-based verification processes.

The structural distinctiveness of nuclear agreements becomes more visible here. 81% of nuclear compliance mechanisms are pre-consented and self-executing. In non-nuclear agreements, only 57% are. Fisher's Exact Test suggests this difference is statistically significant (two-tailed $p \approx 0.04$). The share of unilateral/reactive triggers in non-nuclear (43%) is three times higher than in nuclear (14%). Beyond raw

count, such reactive triggers are also more widely distributed across non-nuclear agreements. For example, state-party request appears in 67% of non-nuclear agreements but only 38% of nuclear ones.

This means the nuclear verification architecture is generally more cooperative and pre-consented in design than other WMDs. Nuclear triggers are typically tied to objective conditions—such as material quantities or activity limits, unlike in non-nuclear agreements, where a substantial share of mechanisms either operate without a clear trigger or depend on loosely defined conditions, giving states greater latitude in determining when compliance scrutiny intensifies. This distinctiveness is likely because nuclear agreements involving superpowers—especially bilateral ones—were negotiated under conditions of mutual deterrence and extreme political sensitivity. Routine agreement triggers and self-reported state-action notifications allowed parties to participate in verification without any side blatantly accusing another of violating the agreement and unsettling deterrence. This may also explain why demonstrated compliance mechanisms are far more common in nuclear agreements than in other WMDs.

3.2.2 Among multilateral treaties, institution-initiated triggers are more common in nuclear agreements

Another notable difference concerns institution-initiated triggers, which appear more commonly in the nuclear domain, though the absolute numbers remain very small (2 nuclear mechanisms vs 0 non-nuclear). Because of these low counts, Fisher’s Exact Test does not establish statistical significance here. However, although the majority of the nuclear agreements observed are bilateral and, consequently, do not have any agreement associations, multilateral nuclear agreements clearly set themselves apart from non-nuclear ones. The CWC and BWC—the two multilateral non-nuclear agreements—have no trigger mechanisms activated by their relevant international bodies.

By contrast, two of the three multilateral nuclear agreements—the CTBT and the Seabed Treaty—empowers established or utilized associations to trigger compliance mechanisms. In both treaties, challenge inspections can be triggered by the association—a responsibility which the CWC and BWC leaves to the discretion of state parties that are inclined to err on the side of activating it.

3.3 Is The Difference Statistically Significant?

Although not every individual comparison reached conventional significance thresholds, combining the tests across trigger mechanisms and inspector arrangements suggests that the governance architecture of nuclear agreements in these domains differs systematically from that of non-nuclear agreements. Using Fisher’s Method to aggregate the individual p-values ($p \approx 0.005$) indicates that the observed differences are unlikely to be explained by random variation alone. This provides quantitative support for the broader conclusion that nuclear agreements exhibit a distinct verification and compliance design template relative to chemical and biological arms-control regimes.

4. AI GOVERNANCE LESSONS

4.1 Which features are plausibly transferable to AI governance?

4.1.1 NTMs for physical AI infrastructure

At first pass, NTMs appear non-transferable to AI governance, since AI development happens in server farms and software environments that are not meaningfully observable by satellite. However, the nuclear NTM logic seems applicable to the hardware layer of AI governance, such as for monitoring or preventing unauthorized operation or construction of datacenters and large-scale advanced semiconductor fabrication.⁴

Fortunately, advanced AI chip fabrication plants share relevant physical properties with the nuclear facilities that NTMs were designed to monitor—they are large, expensive, geographically fixed, and require distinctive infrastructure. Wasil et al. (2024) note that commercial satellite imagery at sub-metre resolution can identify specialised cooling units and the movement of computing equipment associated with data centres. This can potentially detect undeclared large-scale data centre complexes where unauthorized activities may take place, or the construction of new semiconductor fabs. As a result, a chip production moratorium (Al Ramiah et al., 2025; Barnett et al., 2025) — which can advance a number of AI governance goals⁵ — could be monitored through NTM-style remote sensing and satellite surveillance in exactly the way nuclear facilities are monitored. As with nuclear agreements, the protection and legitimization of the use of NTMs could also be embedded into the texts of AI treaties.

4.1.2 Baseline data exchanges

Every major nuclear arms reduction agreement begins with a comprehensive baseline declaration covering relevant facilities, delivery systems, launchers, and warhead quantities. From that point, inspections operate primarily as mechanisms for verifying that reality matches the declared baseline. Declarations create legal obligations and establish common reference points for compliance assessment.

This feature appears transferable to AI governance, particularly at the infrastructure layer. The AI equivalent would not primarily be a registry of AI models—which are mutable and replicable—but rather a mandatory declaration system for frontier-compute infrastructure. States or firms could be required to declare hyperscale datacenters, frontier training clusters, advanced chip inventories, semiconductor manufacturing capacity, and training runs above specified compute thresholds. Inspections and monitoring mechanisms may then verify whether observed infrastructure and compute activity correspond to the declared baseline.

Several existing AI governance proposals already partially reflect this architecture, including AI chip registries (Sastry et al., 2024), data center reporting requirements (Baker et al., 2025; Scher & Thiergart, 2024), and proposals for licensing frontier-scale training runs (Anderljung et al., 2023). The nuclear precedent suggests that such declarations are most effective when they are technically specific and submitted as binding obligations at the outset of an agreement rather than through voluntary or ad hoc disclosure systems.

⁴ These are key levers of AI governance. International regulations can, for example, set restrictions on the size and quantity of large-scale computing facilities to make sure they cannot power the development of AI beyond an agreed-upon threshold. See Wasil et. al (2024)

⁵ For example, a moratorium could slow the growth of global compute supply, thereby constraining states' and AI developers' ability to train models beyond agreed danger thresholds.

However, transferability here depends heavily on the existence of measurable thresholds. Nuclear agreements succeeded partly because missiles, launchers, and warheads were countable objects. Any baseline declaration regime for AI would therefore require relatively precise criteria — such as chip quantities or energy usage — in order to determine what exactly must be declared and verified. Without such thresholds, the baseline exchange may be difficult to enforce.

4.1.3 State-party notification infrastructure for incident reporting

The dense notification regime observed in many nuclear agreements like New START and START I are a good fit for AI incident reporting. Under these agreements, virtually every significant activity involving a treaty-limited item, such as a missile leaving a production facility, a launcher beginning conversion, or a heavy bomber conducting a major exercise, automatically triggers a notification obligation. Since each party receives a continuous stream of notifications about treaty-relevant activities, the obligation creates a transparency layer that functions independently of whether any on-site facility inspections hold.

This may be architecturally feasible for governing frontier AI. Mandatory notification to a bilateral consultative body or a multilateral registry could be required for notable events—a training run exceeding a defined compute threshold; a data centre expanding its GPU capacity; the activation of AI systems in sensitive domains; a large-scale model evaluation or red-team assessment. Yet, it is expedient to flag that such infrastructure in AI governance may not yield the same level of effectiveness that nuclear agreements have. Many of the nuclear events triggering an obligation to notify produce spatial and physical signatures, meaning that they are difficult to conceal and—even in the absence of a notification to the other party—may still be detected by that other party regardless. Logically, this makes the nuclear notification infrastructure work, with each state dissuaded from uncooperative behaviour by the fact that independent detection is not unlikely and may be misinterpreted as aggression or deception.

While AI materials and systems are also capable of producing visible signatures that would make concealment risky (Wasil et al., 2024), AI is far more elusive and more deeply embedded in civilian applications, giving actors substantially greater room for concealment and maneuvering. It is therefore not unreasonable to expect enforcement challenges in AI governance that were far less pronounced in the nuclear domain.

4.1.4 Activity-window access for monitoring frontier training runs

The PNE Treaty and Threshold Test Ban Treaty introduced a verification design that appears rarely elsewhere in the dataset but has important relevance for AI governance: inspector access tied to a specific, time-bounded activity rather than routine access to a standing facility. Under both treaties, inspectors were present during the nuclear explosion itself to observe emplacement procedures, instrumentation and detonation, because the event was transient and could not later be reconstructed with equivalent confidence.

Certain frontier AI training runs share aspects of this verification problem. A training run that exceeds an agreed compute threshold or uses a highly capable novel architecture may be difficult to fully evaluate retrospectively. Post-training audits can inspect outputs, logs, and hardware records, but may not always reconstruct the full developmental process with the same confidence as contemporaneous monitoring.

Some forms of AI governance may therefore eventually require real-time monitoring mechanisms during the execution of especially sensitive training runs rather than relying entirely on post-hoc review.

At the same time, the analogy is only partially transferable. Nuclear detonations are singular physical events with relatively clear boundaries, whereas AI development is more continuous, and iterative. Unlike nuclear explosions, training runs may leave digital artifacts that permit partial retrospective verification. Moreover, the institutional burden of monitoring frontier AI development could be substantially higher than in the nuclear context. TTBT and PNE verification applied to rare, state-conducted events, while frontier AI training may occur more frequently than what can be covered by inspector capacity. Distributed training could further complicate activity-window verification by spreading computation across multiple facilities or jurisdictions (Scher & Thiergart, 2024).

Owing to this complication, the transferability of this feature is conditional rather than straightforward. The nuclear precedent does not imply that continuous inspector presence during AI development is broadly feasible. However, it does suggest that for a narrow class of exceptionally high-risk frontier training runs, governance systems may eventually require some form of contemporaneous monitoring or live-access verification rather than relying solely on retrospective audits.

4.2 Which features are unlikely to transfer to AI governance?

4.2.1 NTMs for software and training processes

While NTMs transfer for physical AI infrastructure, they transfer much less effectively to the governance of AI models themselves, or for the software and computational processes that constitute the core of AI governance concern. Unauthorized AI development may occur on existing compute infrastructure—and inside legitimate facilities—without obvious external markers. Satellite imagery cannot observe what code is running in a data centre, what training data is being used, what capability thresholds a model has crossed, or whether a training run is producing a model with dangerous capabilities. The nuclear governance model's reliance on NTMs as a persistent background monitoring layer has no functional equivalent for AI software verification. Crucially, it is unlikely that better satellites in the future will close this gap.

4.2.2 Reliable state-party inspections in multilateral AI agreements

The party-on-party inspection type—which every bilateral and most multilateral nuclear agreements rely on—is transferable to bilateral agreements between the most advanced AI powers. But its limitations become acute in the multilateral context that broader AI governance regulations would require. An arrangement where one side verifies the other's activities is most effective when both parties have roughly equivalent technical capability to conduct inspections. Nuclear agreements between the US and USSR/Russia typifies this. And US-China agreements on AI will likely replicate this easily, as both states possess frontier AI development capabilities, sophisticated technical talent, and at least nascent interpretability and evaluation tools.

However, this near-symmetry does not extend to multilateral AI agreements that aspire to near-universal membership, as such an agreement would include states with vastly different technical capacities to

conduct or receive meaningful AI inspections. Party-on-party inspection assumes that the inspecting state can competently evaluate what it observes; for example, that its inspectors can identify whether a training run's architecture raises concerns, interpret capability evaluation results, and detect evasion through technical means. This assumption was warranted in the nuclear context, because missile dimensions, warhead counts, launcher configurations and other physical objects being verified were easily assessable. Yet, AI inspections differ categorically and would require deep familiarity with evaluation methods that are themselves rapidly evolving and not widely diffused (Tong et al., 2026).

4.2.3 Capabilities thresholds as precise triggers

As we have stressed, nuclear trigger mechanisms are built on objectively measurable quantities. For example, a missile with a range exceeding 500km, a test explosion with a yield exceeding 35 kilotons. The precision and unambiguity of these thresholds enable the notification and inspection architecture in nuclear agreements to work, because they are clear enough that each party knows when a notification is required and what constitutes non-compliance.

Capability thresholds in AI governance are also relevant and already widely proposed (Karnofsky, 2024; Hendrycks et al., 2025), but they are riddled with many problems that complicates their use as precise triggers. The first is that AI capabilities exist on a spectrum, and are therefore difficult to define unambiguously. For example, “human-level reasoning” or “automated AI R&D” are capability levels that are contestable. Even currently, experts disagree regarding what the same AI systems are capable of (Bubeck et al., 2023; Marcus, 2023; Schaeffer et al., 2023). In the future, different evaluators may equally reach different conclusions about whether a threshold has been crossed.

Relatedly, while nuclear systems have relatively predictable relationships between inputs and destructive capacity, AI systems may exhibit emergent capabilities and are highly context-specific. A model may be deemed harmless in one setting, but dangerous capabilities may emerge from interaction effects between systems (Dafoe et al., 2021; Borghoff et al., 2025), agentic scaffolding or tool integration. This creates governance difficulties because capability thresholds may depend not only on the model itself but also on surrounding infrastructure and deployment conditions that may be difficult to sufficiently capture in legislation. These considerations create instability in governance triggers that might complicate their sustained use in imposing obligations in agreements.

5. LIMITATIONS

The nuclear dataset contains 13 agreements and 105 compliance mechanisms; the non-nuclear dataset contains 3 agreements and 14 mechanisms. This imbalance places limits on the statistical comparisons presented in this analysis and warrants acknowledgment.

The most significant risk is that patterns identified within the nuclear dataset — such as the prevalence of state-party action triggers or the layered agreement-notification architecture — reflect genuine design features of nuclear governance, but cannot be tested against a non-nuclear comparison class of equivalent size. With only three non-nuclear agreements, any cross-group statistical comparison is sensitive to the characteristics of individual agreements: the BWC’s verification absence, for instance, meaningfully depresses the non-nuclear cooperative trigger percentage in a way that a larger sample might not sustain.

This imbalance is partly a function of the scoping decisions described above, and partly a function of the domain itself — there are simply fewer multilateral WMD agreements than nuclear superpower agreements.

Findings should therefore be read with appropriate caution. Where statistical differences between nuclear and non-nuclear are large, they are likely robust to sample size limitations. Where differences are smaller or where they depend on the characteristics of a single non-nuclear agreement, they are better treated as directional indicators than as definitive findings.

6. CONCLUSION

This paper asked whether nuclear agreements follow a distinct governance design template relative to other WMD agreements, and whether that template meaningfully transfers to AI governance. The findings suggest that nuclear agreements do exhibit a distinct verification architecture. Across inspector arrangements and trigger mechanisms, nuclear agreements rely more heavily on party-on-party inspections, treaty-protected NTMs, layered verification tools, and cooperative or pre-consented trigger mechanisms. Their compliance systems are generally continuous and routine rather than primarily adversarial or challenge-based. Combined statistical testing suggests these differences are unlikely to be random.

These patterns appear closely tied to the physical characteristics of nuclear systems themselves. Nuclear weapons programs produce visible infrastructure, measurable outputs, and relatively stable relationships between physical inputs and destructive capacity. This made it possible for nuclear governance to evolve around NTMs, countable thresholds, and structured inspection regimes in ways that were less feasible for chemical and biological weapons governance. However, the transferability of the nuclear model to AI governance is uneven. The findings suggest that the most transferable features of nuclear governance are those tied to the physical infrastructure supporting frontier AI development rather than software systems themselves. NTMs, baseline declarations, notification systems, and some forms of monitoring may plausibly transfer to the governance of datacenters, semiconductor fabrication facilities, and compute infrastructure. This is helpful, as hardware governance creates conditions that make dangerous AI development harder and more observable, but it does not solve the underlying verification problem that makes AI governance difficult—the difficulty of inferring capability from infrastructure alone, or of detecting a prohibited training run with limited access to the computational process itself.

The findings also complicate the common assumption in AI governance discourse that the nuclear model is primarily institution-centric. In reality, the dominant pattern across the agreements studied here is reciprocal state verification between technologically sophisticated rivals rather than centralized international inspection. The nuclear model therefore appears less like a universal “IAEA for AI” and more like a governance architecture built around material visibility, reciprocal vulnerability, and a relatively small number of technically capable actors.

The conclusion this paper reaches is therefore neither that nuclear governance is a reliable template for AI nor that the comparison is uninformative. It is that the comparison is instructive in a more specific and more sobering way than advocates typically suggest. The nuclear model offers a workable architecture for

governing the physical substrate of AI development. But it offers little guidance for governing AI capabilities themselves.

ACKNOWLEDGMENTS

This research evolved from a collaborative project that began as part of a research sprint conducted by the Alva Myrdal Centre for Nuclear Disarmament. I thank Lucie Fayoux and Natalia Luers for discussions that influenced the scoping decisions and direction of this research, and Sophia Hatz for permission to use the AMC dataset.
